1. Intro | Business Understanding

1.1 Background

Every year car accidents cause hundreds of thousands of deaths worldwide. According to a research conducted by the World Health Organization (WHO) there were 1.35 million road traffic deaths globally in 2016, with millions more sustaining serious injuries and living with long-term adverse health consequences. Globally, road traffic crashes are a leading cause of death among young people, and the main cause of death among those aged 15 – 29 years. Road traffic injuries are currently estimated to be the eighth leading cause of death across all age groups globally, and are predicted to become the seventh leading cause of death by 2030[1].

Leveraging the tools and all the information nowadays available, an extensive analysis to predict traffic accidents and its severity would make a difference to the death. Analyzing a significant range of factors, including weather conditions, locality, type of road and lighting among others, an accurate prediction of the severity of the accidents can be performed. Thus, trends that commonly lead to severe traffic incidents can help identifying the highly severe accidents. This kind of information could be used by emergency services, to send the exact required stuff and equipment to the place of the accident, leaving more resources available for accidents occurring simultaneously. Moreover, this severe accident situation can be warned to nearby hospitals which can have all the equipment ready for a severe intervention in advance.

Consequently, road safety should be a prior interest for governments, local authorities and private companies investing in technologies that can help reduce accidents and improve overall driver safety and either some other mobile applications to warn Civilians.

1.2 The Problem

Data that might contribute to determining the likeliness of a potential accident occurring might include information on previous accidents such as road conditions, weather conditions, exact time and the place of the accident, type of vehicles involved in the accident, information on the users involved in the accident and occurs the severity of the accident. This project aims to forecast the severity of accidents with previous information that could be given by a witness informing the emergency services.

1.3 Interest

Governments should be highly interested in accurate predictions of the severity of an accident, in order to reduce the time of arrival and to make a more efficient use of the resources, and thus save a significant amount of people each year. Others interested could be private companies investing in technologies aiming to improve road safeness and Finally, wouldn't it be great if there is an application that could warn people, given the weather and the road conditions about the possibility of them getting into a car accident and how severe it would be, this way they would drive more carefully or even change your travel if you are able to.

2. Data Preparation

2.1 Data Source

This Data Can be Found on The Following Kaggle data set

Please [Click Here](#).

2.2 Feature Selection

The data is divided in 5 different data sets, consisting of all the recorded accidents in France from 2005 to 2016. The characteristics data set contains information on the time, place, and type of collision, weather and lighting conditions and type of intersection where it occurred. The places data set has the road specifics such as the gradient, shape and category of the road, the traffic regime, surface conditions and infrastructure. On the user data set it can be found the place occupied by the users of the vehicle, information on the users involved in the accident, reason of traveling, severity of the accident, the use of safety equipment and information on the pedestrians. The vehicle data set contains the ow and type of vehicle, and the holiday one labels the accidents occurring in a holiday. All data sets share the accident identification number.

An initial analysis of the data was performed for the selection of the most relevant features for this specific problem, reducing the size of the dataset and avoiding

redundancy, [Click Here](#) to take a look. With this process the number of features was reduced from 54 to 28.

2.3 Data Description

The dataset that resulted from the feature selection consisted in 839,985 samples, each one describing an accident with 29 different features.

These features are the following:

From the characteristics dataset: lighting, localisation, type of intersection, atmospheric conditions, type of collisions, department, time and the coordinates which are described in the Kaggle dataset here. In addition, two new features were crafted, date to perform a seasonality analysis of the accident severity and weekend indicating if the accident occurred during the weekend or not.

Regarding the place's dataset, the selected features where: road category, traffic regime, number of traffic lanes, road profile, road shape, surface condition, situation, school nearby and infrastructure.

The users dataset was used to craft some new features:

number of users: total number of people involved in the accident.

pedestrians: whether there were pedestrians involved (1) or not (0).

critical age: whether there were users between 17 or 31 years old involved in the accident.

severity: maximum gravity summarized by any user involved in the accident.

Unscathed or light injury (0), hospitalized wounded or death (1)

The holiday dataset was used to add a last feature, labeling the accidents which occurred in a holiday.

2.4 Data Cleaning

Essentially, I cleaned the data to process of giving a proper format for its further analysis. Rest step was to deal with missing values and outliers. Initially the latitude, longitude and road number were dropped from the data frame as more than a 50% of its values were **NaN** or **0** which is an outlier in this case.

The analysis was divided in two groups of features. The first group had in all features a label which described other cases, for instance the feature describing the atmospheric conditions had a value of 9 for any other atmospheric condition not labeled with the other 8 values. Therefore, the missing values and outliers were replaced with the other cases label for the features of atmospheric conditions, type of collision, road category and the surface conditions. For the second group of features instead, the distribution of their values was analyzed. Then two features were dropped, the infrastructures and reserved lanes, as the outliers represented more than 75% of its data. Finally with the rest of the features with missing values, the traffic regime, the number of lanes, the road profile and shape and the situation at the time of the accident, the NaN and outliers were replaced with the feature's most popular value.

Last format changes were performed to the school and department values. The school feature had all samples divided either in the 0 or the 100 values, thus all the 100 values were replaced with the number (1) Similarly the department

feature had an extra (0) added at the units position, so all values were divided by 10.

Regarding the type of the data, all features had a coherent data type except for the date feature which was defined with the string type. I used the two data function of pandas to define the date feature with the datetime type. After all, **24** features remained.

3. Exploratory Data Analysis

First, the distribution of the target's values was visualized. The plot confirmed that it is a balanced labeled dataset as the samples are divided 56–54 with more cases of lower severity. Then a seasonality analysis was performed, visualizing the global trend of daily accidents as well as the amount of accidents grouped by years, month of the year, and day of the week.

Figure 1 – The Total amount of accidents per year

The previous Figure shows that the number of traffic accidents decreased over the years from 2005 to 2013, after which the trend became stable. Analyzing the yearly trend there is a seasonal pattern where the number of accidents increase around March and then again in September. This pattern can be seen in following two figures.

Figure 2 – Accident per day during years 2013 – 2016

Figure 3 – Accident per month from 2005 to 2016

During the day of the week we do not see a significant difference between accident in the days as in Figure4. But we notice a trend during the week with more accidents on Friday, on contrary, Sunday is the day with less recorded accident.

Figure 4 – Accident per weekdays from 2005 – 2016

Lastly, when we take a look on analyzing the accidents per hour, we see clearly two spikes, The First at **8am**, when people usually go to work and the other Spike between **5 – 6 pm**, when people return homes. The number of accidents decreases between these two spikes, nothing unusual just a normal and clear pattern as we see in Figure 5 below.

The trend of highly severe accidents is proportional to the global trend, for both the accidents divided per month of the year and per day of the week. Same thing happens with the amount of highly severe accidents by hour of the day as we can see on Figure 5. One aspect to highlight from the hourly trend is that the proportion of severe accidents from noon to morning is higher, to be precise, the percentage of severe accidents from 9pm to 6am is 50.67% of the total amount of accidents occurring between these hours, while from 7am to 8pm is 42.41%. Due to the results of the former analysis, to features were added, month and day as the day of the month.

The next statistical analysis was the correlation of the features with the severity of an accident. The Pearson correlation showed weak or null correlation with all features. Further visualizations were performed for a better understanding of the data. Some conclusions of this analysis were for instance that accidents involving people above 84 years old tend to have a high severity.

4. Predictive Modeling

Different classification algorithms have been tuned and built for the prediction of the level of accident severity. These algorithms provided a supervised learning approach predicting with certain accuracy and computational time. These two properties have been compared in order to determine the best suited algorithm for this specific problem.

Firstly, the 839.985 rows were split 80/20 between the training and test sets, afterwards an additional 80/20 split was performed among the training samples creating the validation set for the development of the models. Then the data was standardized giving zero mean and unit variance to all features.

Four different approaches were used:

- Decision Tree
- Random Forest Logistic Regression
- K-Nearest Neighbor
- Supervised Vector Machine

The same methods were performed with each algorithm. With the train and validation sets the best hyperparameters were selected and using the test set, the accuracy and computational time for the development of the models were calculated.

The decision tree model was upgraded to the random forest. With the default random forest, the features were sorted by impurity-based importance in the prediction of the severity. Thus, the 10 least important features were dropped to decrease the computation complexity for the KNN and SVM models. Keeping with **13** features the accuracy stayed the same and the computational time decreased significantly. After evaluating the parameters for each algorithm these were the models.

- Random Forest: 10 decision trees, maximum depth of 12 features and maximum of 8 features compared for the split.

- Logistic Regression: $c=0.001$.
- KNN: $k=16$
- SVM: size of the training set= 75,000 samples.

The following visualizations show how the parameters for KNN and SVM models were selected. The SVM model is computationally inefficient with huge sample sets. Therefore, an equilibrium between accuracy and computational time was found evaluating different training sizes. The training set was reduced from 537,590 to 75,000 rows. On Figure 7, the accuracy is increasing as the training size does, however Figure 9 shows how this comes with an important increasing of the computational time.

Figure 6 – Accuracy of KNN models increasing the value of K

Figure 7 – Accuracy of SVM increasing the training sample's size

Figure 8 – Computational time of SVM increasing the training sample's size

5. Model Evaluation

The metrics used to compare the accuracy of the models are the Jaccard Score, f1-score, Precision and Recall. This table reports the results of the evaluation of each model.

Algorithm	Jaccard	f1-score	Precision	Recall	Time(s)
Random Forest	0.722	0.72	0.724	0.591	6.588
Logistic Regression	0.661	0.65	0.667	0.456	6.530
KNN	0.664	0.66	0.652	0.506	200.58
SVM	0.659	0.65	0.630	0.528	403.92

In this case, the recall is more important than the precision as a high recall will favor that all required resources will be equipped up to the severity of the accident. The logistic regression, KNN, and SVM models have similar accuracy, however the computational time from the regression is far better than the other two models. With no doubt the Random Forest is the best model, at the same time as the log. res. it improves the accuracy from 0.66 to 0.72 and the recall from 0.45 to 0.59.

Figure 9: ROC curve from the results of the Random Forest model.

I also evaluated the best model using their ROC curves. In this particular problem, lower false positive rate is less important than higher true positive rate. In other words, it is more important to properly predict the high-severity accidents properly, if there is room for doubt it is better to prevent.

6. Conclusion

After analyzing the relationship between severity of an accident and some characteristics which describe the situation that involved the accident, I could say that features such as atmospheric conditions, the lighting or being a holiday would be the most relevant ones, yet I identified the department, the day and time of the

accident, the road category and type of collision among the most important features that affect to the gravity of the accident. I built and compared 4 different classification models to predict whether an accident would have a high or low severity. Now, these models can have multiple application in real life. For instance, imagine that emergency services have an application with some default features such as date, time and department/municipality and then with the information given by the witness calling to inform on the accident they could predict the severity of the accident before getting there and so alert nearby hospitals and prepare with the necessary equipment and staff. Also, by identifying the features that favor the most the gravity of an accident, which could be tackled by improving road conditions or increasing the awareness of the population.
